## ABSTRACT

The electrochemical properties of nanocomposite  $\text{SnO}_2$ –Se thin film prepared by pulsed laser deposition method have been investigated by cyclic voltammetry and charge/discharge measurements. A large reversible specific capacity of  $958.8 \text{ mAh g}^{-1}$  in  $\text{SnO}_2$ –Se/Li cell cycled between 0.01 and 3.0 V is achieved. Our results have demonstrated that nanocomposite  $\text{SnO}_2$ –Se exhibits larger capacity and better cycle performance than pure  $\text{SnO}_2$  and SnSe. The electrochemical reaction mechanisms of  $\text{SnO}_2$ –Se with lithium are examined by X-ray diffraction, high resolution transmission electron microscopy, selected-area electron diffraction and spectroelectrochemical measurements. The reversible oxidation/reduction reaction of  $\text{SnO}_2$  and selenidation/reduction reaction of SnSe are revealed.

## 1. Introduction

Tremendous research effort has been devoted to the exploration of novel types of anode materials with larger specific capacities and longer cycle lives instead of the presently used carbonaceous and graphite electrode materials. Tin oxide-based materials as an anode have been attractive in the field of lithium-ion batteries due to a high theoretical capacity of  $\text{Li}_{4.4}\text{Sn}$  ( $994 \text{ mAh g}^{-1}$ ) [1]. However, the huge volume change of Li–Sn alloys (above 300% for pure Sn) [2,3] results in the stress-induced pulverization and poor cycling stability of the electrode. Several strategies have been adopted for overcoming these drawbacks of tin oxide-based materials. One of the most common approaches is to employ nanosized materials as recently reviewed [4]. For example,  $\text{SnO}_2$  electrodes with various nanostructures have been reported, such as columnar grains [5], spherical particles [6], hollow [7], thin film [8], nanowires [9],

nanofibers [10] and macroporous structure [11]. Nanostructures of the electrodes can accommodate volume changes, which can remarkably improve the cyclic performance of the tin oxide-based electrodes [5–11]. On the other hand, Xie et al. have reported that the diffusion coefficients  $D_{\text{Li}}$  values are  $10^{-15}$ – $10^{-13} \text{ cm}^2 \text{ s}^{-1}$  for  $\text{SnO}_2$  films by galvanostatic intermittent titration technique (GITT) and suggest that Li-ion diffusion kinetics can be further enhanced by the introduction of other phases into tin oxide thin films [12]. Element doping, such as Zn [13], Sb [14] and F [15], into those nanostructured tin oxides have been confirmed as an effective way. These doped elements could lead to the formation of finer surface morphology and smaller crystallite size, which would provide more reaction sites and facilitate the diffusion of Li, and made it more capable of accommodating the volume changes in cycling. Besides, more researches have been focused on synthesis of various tin-based oxides composites to achieve superior electrochemical behaviors. Fan et al. reported ordered nanostructured tin oxides/carbon composites exhibits a better cyclic performance than pure nano- $\text{SnO}_2$  electrode [16].  $\text{SnO}_2$ –CuO nanocomposite studied by Ma et al. showed a reversible capacity of  $752 \text{ mAh g}^{-1}$  and better

cycleability compared with nano-SnO<sub>2</sub> [17]. SnO<sub>2</sub>–MnO film delivered by Zhu et al. had 1188.3 mAh g<sup>−1</sup> of initial discharge capacity and very good capacity retention of 656.2 mAh g<sup>−1</sup> up to the 30th cycle [18]. Meduri et al. found hybrid tin oxide nanowires containing of Sn, SnO and SnO<sub>2</sub> exhibit a reversible storage capacity greater than 800 mAh g<sup>−1</sup> over 100 cycles [19]. All these results indicate the diversification of the composites in tin oxide electrode can be beneficial to its electrochemical property.

In our previous work, Fe<sub>2</sub>O<sub>3</sub>–Se [20] and ZnO–Se [21] nanocomposites showed larger reversible specific capacities and better cyclic stabilities than pure Fe<sub>2</sub>O<sub>3</sub> and ZnO, respectively. After discharge, the products were revealed to be Fe or ZnLi, Li<sub>2</sub>O and Li<sub>2</sub>Se. After charge, metal oxides and selenides were produced. Apparently, these systems with two anions have its unique advantage and the reaction mechanisms with lithium are rather complicated and interesting. In this paper, we will report a novel thin film electrode based on the mixture of SnO<sub>2</sub> and Se as well as its electrochemical properties and reaction mechanisms for the first time. Nanocomposite SnO<sub>2</sub>–Se thin films were fabricated by pulsed laser deposition (PLD) method. The electrochemical behavior and physical properties of nanocomposite SnO<sub>2</sub>–Se thin film were characterized by galvanostatic cycling, cyclic voltammetry, *in situ* UV–Vis absorption spectra, high resolution transmission electron microscopy (HRTEM) and selected-area electron diffraction (SAED). The motivation of this study is to explore the influence of inducing Se into SnO<sub>2</sub> thin film as an anode material for lithium-ion batteries and to elucidate the electrochemical reaction mechanism of nanocomposite electrode with lithium.

## 2. Experimental

A PLD system for the fabrication of thin films in a vacuum chamber was described previously [22]. Experimental conditions for depositing thin films are described as follows: A 355 nm laser beam from a Q-switched Nd: yttrium aluminum garnet laser (Spectra Physics GCR-150) with a pulsed repetition rate of 10 Hz and a pulsed width of 5 ns was focused onto the surface of the target. The incident angle between the laser beam and the target surface normal was 45°. The laser intensity was about 2 J cm<sup>−2</sup>. The distance between the target and the substrate was 4 cm. The sputtering chamber was evacuated below 10<sup>−3</sup> Pa during deposition. Composite target consisting of SnO<sub>2</sub> and Se were obtained by cold pressing SnO<sub>2</sub> powder (99.95%, Alfa Aesar) and Se powder with a molar ratio of 1:0.8. The films were deposited on a stainless steel substrate at room temperature. The thickness of the as-deposited films is about 80 nm for the depositing time of 30 min. Weight of thin film was directly obtained by subtracting the original substrate weight from total weight of substrate and deposited thin film onto its surface, which were examined by electrobalance (BP 211D, Sartorius), and was about 0.05 mg with the area of 1.0 cm<sup>2</sup>.

X-ray diffraction (XRD) patterns and the morphology of the SnO<sub>2</sub>–Se thin film electrodes were recorded by a Rigata/max-C diffractometer with Cu K $\alpha$  radiation ( $\lambda = 1.5406$  Å) and scanning electron microscopy (SEM) (Cambridge S-360), respectively. HRTEM and SAED measurements were carried out by a JEOL 2010 TEM at 160 kV accelerating voltage. An energy-dispersive X-ray analysis (EDX, Kevex EDX spectrometer) coupled with the microscope was used to determine the chemical composition of the products. *In situ* spectroelectrochemical measurements were further utilized to obtain the *in situ* UV–Vis absorption spectra of the deposited thin film through the electrochemical reaction, where SnO<sub>2</sub>–Se thin film was deposited on Au coated quartz plate and used as a working electrode. Details for the *in situ* spectroelectrochemical measurements have been described elsewhere [23].

For the electrochemical measurements, the cells were constructed by using the as-deposited SnO<sub>2</sub>–Se thin film as a working electrode and two lithium sheets as a counter electrode and a reference electrode, respectively. The electrolyte consisted of 1 M LiPF<sub>6</sub> in a nonaqueous solution of ethylene carbonate (EC) and dimethyl carbonate (DMC) with a volume ratio of 1:1 (Merck). Charge–discharge measurements were performed at room temperature with a Land BT 1–40 battery test system. The cells were cycled between 0.01 V and 3.0 V vs. Li/Li<sup>+</sup> at a current density of 15  $\mu$ A cm<sup>−2</sup>.

To avoid the exposure to air or water, the model cells at different stages including the as-deposited, discharged to 0.01 V and recharged to 3.0 V were dismantled in an Ar-filled glove box and the electrodes were rinsed in anhydrous DMC to eliminate residual salts.

## 3. Results and discussion

Pulsed laser deposition method is generally considered to be effective in fabricating thin film with high deposition rate, easy control over film thickness, and original bulk target transferring. However, PLD process is rather complicated if a mixed target is ablated. In order to identify the composition and structure of the as-deposited thin films, XRD, TEM and SAED measurements were carried out and the results are shown in Fig. 1. Fig. 1(a) shows XRD pattern of the as-deposited thin films. Three diffraction peaks appearing at  $2\theta = 26.6$ ,  $33.9$ , and  $51.9^\circ$  can be assigned to (110), (101), and (211) reflection of SnO<sub>2</sub> (JCPDS 77-0451). However, no any peak from Se is observed. This may be due to the size of its particles smaller than the X-ray coherence length and thus cannot be detected by XRD technology. On the other hand, crystalline lattices can be clearly observed in the high resolution TEM image of SnO<sub>2</sub>–Se thin film (Fig. 1(b)). They can be indexed to (110) plane of SnO<sub>2</sub>. SAED pattern in this region shown in Fig. 1(c) exhibits some clear concentric rings and some spots. All d-spacings corresponding to these rings and spots derived from the SAED spectra are listed in Table 1 and could be assigned to SnO<sub>2</sub> (P4<sub>2</sub>/mmn) and Se (P3<sub>1</sub>21). These results indicate that the as-deposited film mainly consists of SnO<sub>2</sub> and Se. According to EDX spectra (not shown here), the mole ratio of Sn and Se is estimated to be about 2.65: 1.00. The inconsistent stoichiometry between the thin film and the original target implies the loss of Se during the laser ablation.

The galvanostatic cycling curves of nanocomposite SnO<sub>2</sub>–Se/Li cells at room temperature is shown in Fig. 2(a). It was cycled between 0.01 and 3.0 V at a current density of 15  $\mu$ A cm<sup>−2</sup>. The open-circuit voltage of the cell lies at 1.9 V. There are three sloping discharge plateaus appearing at 1.54, 0.91 and 0.33 V. The initial discharge capacity of 1188.6 mAh g<sup>−1</sup> is obtained, corresponding to about 6.5 Li per 0.726 SnO<sub>2</sub>:0.274 Se unit (referred as SnO<sub>2</sub>–Se unit in the following text), which is close to its theoretical capacity of 1267.4 mAh g<sup>−1</sup>. The plateau at 0.91 V vanished in the second discharge, indicating an irreversible electrochemical reaction while the plateau at 1.54 V was slightly declined to 1.46 V. The subsequent charging curves are identical to that in the first cycle. The second discharge process of the cell yields a reversible discharge capacity of about 959 mAh g<sup>−1</sup>, corresponding to 5.2 Li per SnO<sub>2</sub>–Se unit. After the 100th cycles, a reversible capacity of 773.7 mAh g<sup>−1</sup> could be obtained, indicating excellent capacity retention of the thin film electrode with the loss of capacity less than 0.19% per cycle. Cycling performance and coulombic efficiency of SnO<sub>2</sub>–Se thin film electrodes as a function of the cycle number are presented in Fig. 2(b). The discharge capacities of pristine SnSe thin film from literature [24] and SnO<sub>2</sub> thin film from our own work are also included for comparison. In the initial 120th cycles, the coulombic efficiency can be excellently kept over 96%. Besides, the specific capacity of

$\text{SnO}_2$ -Se thin-film electrode exhibited much better stability than that of other two and only 19% of the reversible discharge capacity was declined after 100 cycles. Apparently, the addition of Se can highly improve the electrochemical behavior of  $\text{SnO}_2$ .

In order to highlight the electrochemical performance of the present material, a comparison of  $\text{SnO}_2$ -Se thin film cathode prepared in this study with those of previous works has been operated. The results are summarized in Table 2. Due to the addition of pure Se, the reversible capacity of  $\text{SnO}_2$ -Se thin film prepared by PLD can be quite high with a relatively large initial capacity of  $1188.6 \text{ mAh g}^{-1}$ . Moreover, the cyclability of this thin film material is also extremely outstanding, which indicates that a prominent improvement of the electrochemical behavior has been reached by synthesis of the  $\text{SnO}_2$ -Se nanocomposited thin film.

Fig. 2(c) presents the first three cyclic voltammograms for the as-deposited nanocomposite  $\text{SnO}_2$ -Se between 0.01 and 3.0 V measured at a scan rate of  $0.2 \text{ mV s}^{-1}$ . Four cathodic current peaks at 1.46, 1.33, 0.91 and 0.25 V are observed in the initial reduction process. The peak at 0.91 V disappeared in the subsequent cycles. There are three anodic peaks at about 1.77, 0.98 and 0.48 V in the initial charging process, all of which have a good repetitiveness in the subsequent cycles, indicating that the reactions were highly reversible. The couple of reduction and oxidation peaks at about 0.25 V during the discharge and at 0.48 V during the charge cycles should mainly result from the alloy reaction of Sn with Li [2,27,28]. The cathodic peak at 0.9 V disappeared in subsequent cycles could possibly be attributed to the irreversible reaction of  $\text{SnO}_2$  [6] as well as solid state electrolyte interface (SEI) film [21]. In the second cycle, a new peak at 0.55 V emerged in the discharging process. This peak remains well in the third cycle, indicating a new electrochemical reaction.

Fig. 3(a), (b) and (c) shows the morphology of the as-deposited, discharged and charged  $\text{SnO}_2$ -Se thin films, respectively. It can be seen that the as-deposited thin film is a flat film consisting of nanosized  $\text{SnO}_2$ -Se particles. After discharging to 0.01 V, the surface morphology is mostly changed and becomes quite different from the initial film (Fig. 3(b)), whereas the components are the same as the as-deposited film according to EDX spectra. Apparently,

**Fig. 2.** (a) Galvanostatic cycling curves in a voltage range of 0.01–3.0 V for the as-deposited  $\text{SnO}_2\text{-Se}$  thin film at a current density of  $15 \mu\text{A cm}^{-2}$ ; (b) Coulombic efficiency of  $\text{SnO}_2\text{-Se}$  thin film and Cycling performance of  $\text{SnO}_2\text{-Se}$  thin film,  $\text{SnO}_2$  thin film,  $\text{SnSe}$  thin film as a function of cycle number; (c) The first three cyclic voltammograms of the as-deposited  $\text{SnO}_2\text{-Se}$  thin film.

the surface becomes rough and the particles aggregate together to form large grains. It should be attributed to the electrochemical decomposition of  $\text{SnO}_2\text{-Se}$  and volume expansion during the formation of  $\text{SnLi}$  alloy. The grains on the surface are most likely due to the agglomeration of nano-size particles and electrolyte interface surrounding the agglomerates. After recharging to 3.0 V (Fig. 3(c)), the large grains are decomposed and shrinking. The size of the grains is obviously reduced. The remarkable morphology changes during discharge and charge imply the huge phase transformation and volume change of the thin film in lithiation/delithiation process.

In order to gain insight into the reaction mechanism of  $\text{SnO}_2\text{-Se}$  thin film with lithium, *ex situ* TEM and SAED measurements were employed to detect the composition and structure of the lithiated and delithiated thin films. Fig. 4(a) shows the typical TEM image of

the lithiated  $\text{SnO}_2\text{-Se}$  thin film. SAED pattern in this region (Fig. 4(b)) exhibits some rings made up of discrete spots and some bright particles, which can be indexed to  $\text{Li}_{22}\text{Sn}_5$ ,  $\text{Li}_2\text{Se}$  and  $\text{Li}_2\text{O}$  according to Table 1. The result confirms the decomposition of  $\text{SnO}_2\text{-Se}$  and the formation of  $\text{Li}_{22}\text{Sn}_5$ ,  $\text{Li}_2\text{Se}$  and  $\text{Li}_2\text{O}$  after discharging to 0.01 V. HRTEM image after the thin film recharging to 3.0 V is shown in Fig. 5(a). The crystal lattices clearly observed can be attributed to (111) plane of  $\text{SnO}_2$ . The corresponding SAED pattern (Fig. 5(b)) exhibits some clear concentric rings, indicating nanosized polycrystalline nature of the delithiated thin film. After calculation, all d-spacings derived from the SAED can be indexed to  $\text{SnO}_2$  and  $\text{SnSe}$  (Table 1). The spacing group of  $\text{SnO}_2$  after charged is  $\text{Fm}\bar{3}\text{m}$ , which is different from that of the deposited thin film.

As we considered that the structure would change and the formation of new products in the electrochemical reaction of  $\text{SnO}_2\text{-Se}$  thin film electrode might cause different optical absorption characteristics over the visible region, it should be believed that the *in situ* UV–Vis absorption spectra based on as-deposited  $\text{SnO}_2\text{-Se}$  thin film could provide some information on the lithiation reaction. Fig. 6(a) and (b) shows *in situ* UV–Vis absorption spectra collected at various states ( $x$  values) of the initial discharge and charge cycle of  $\text{SnO}_2\text{-Se/Li}$  cell at room temperature, respectively.  $\text{SnO}_2\text{-Se}$  thin film electrode was deposited on Au coated quartz substrate at room temperature. During the initial discharge and charge processes, the thin-film electrodes show strong absorption from 500 nm to 900 nm. The shapes of absorption spectra are alike during the discharging and charging processes of  $\text{SnO}_2\text{-Se/Li}$  cell, without any shift of the absorption peaks when Li number increases and decreases. In addition, a progressive increase and decrease of the *in situ* UV–Vis absorption spectra intensity are observed when the Li ions are reduced to 0.01 V and further oxidized to 3.0 V in the discharge and charge cycle, respectively. In order to compare the absorbance change of the discharge and charge processes, the absorbance at 698 nm as a function of  $x$  value are presented in Fig. 6(c). It can be seen that the absorbance changes exhibit an irreversible feature in initial discharging and charging processes and a reversible reaction in second cycle, which is similar to its electrochemical behavior mentioned above. At the  $x$  value more than about 3.5, the amplitudes of all *in situ* absorbance spectra dramatically increases/decreases during discharging/charging, which should be caused by alloy/dealloy reaction of Sn

**Fig. 3.** SEM images of the  $\text{SnO}_2$ –Se thin film for (a) the as-deposited; (b) after the discharging to 0.01 V and (c) after the recharging to 3.0 V.

with Li. Besides, the differences of absorbance spectra between the first and second discharging processes provide an evidence that the charged product is not the same as the original.

Based on the above data, the electrochemical reaction mechanism of  $\text{SnO}_2$ –Se with lithium involving the following steps is proposed.

Initial discharging process:

**Fig. 4.** (a) *Ex situ* high resolution TEM images and (b) SAED spectrum of  $\text{SnO}_2$ –Se thin film electrodes after the discharging to 0.01 V.

Subsequent cycles:

These steps during the discharge and charge processes agree with CV curves, as shown in Fig. 2(c). In the initial discharge, the peak at 0.91 V is caused by solid state electrolyte interface (SEI) film. Cathodic peaks at 1.46 and 1.33 V in the second cycle could be attributed to the decomposition reaction of  $\text{SnO}_2$  (Reaction (1)). The wide cathodic peaks at 0.40 V and 0.25 V corresponds to the lithium

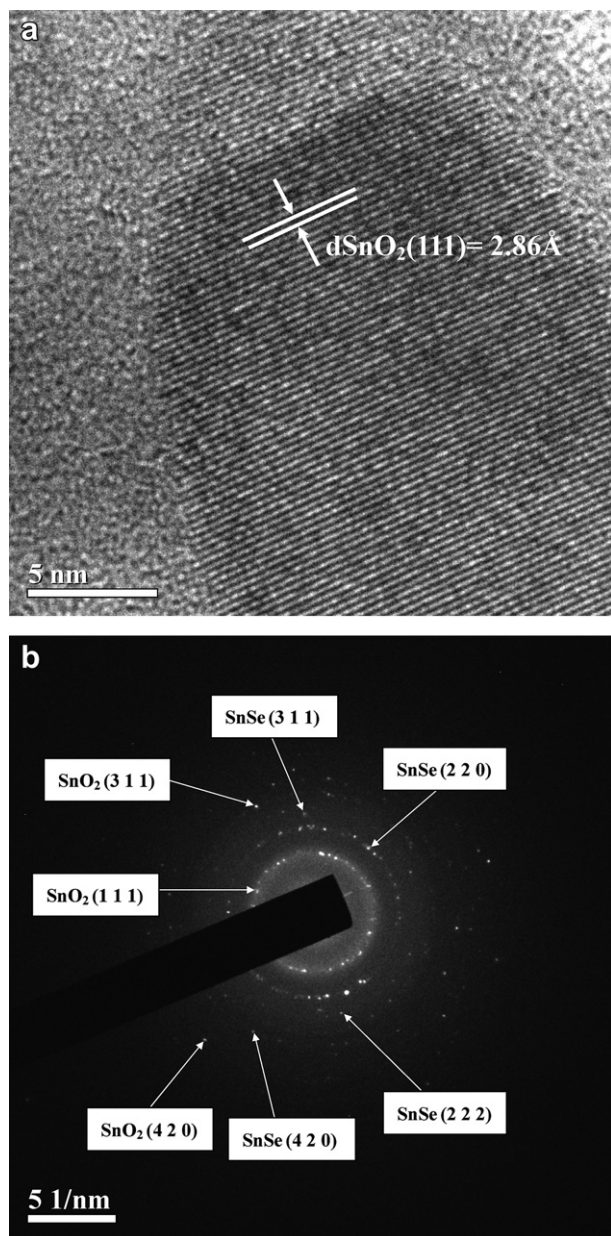

Fig. 5. (a) *Ex situ* high resolution TEM images and (b) SAED spectrum of  $\text{SnO}_2$ -Se thin film electrodes after the charging to 3.0 V.

alloying reaction of Se and Sn (reactions (2) and (3)). The cathodic peaks from these decomposition reactions of  $\text{SnO}_2$  and  $\text{SnSe}$  seem almost overlapped in the subsequent cycles. In the charging process, the peak at 0.48 V is the dealloying reaction of  $\text{Li}_{4.4}\text{Sn}$  (reaction (4)). The anodic peaks at about 0.98 and 1.77 could be attributed to the formation of  $\text{SnO}_2$  and  $\text{SnSe}$ .

Reactions (1)–(3) occur in the first discharge process with the structure transformation of the initial polycrystalline  $\text{SnO}_2$  and Se. In reaction (1),  $\text{SnO}_2$  and Li produce nanosized Sn and  $\text{Li}_2\text{O}$ . In reactions (2) and (3), Se and Sn could alloy with lithium during further discharge. The subsequent cycling processes involved reactions (4)–(6) are completely reversible. It can explain the repeatability of CV curves. These reactions includes alloy/dealloy reactions of Sn with Li, the oxidation/reduction reaction between Sn and  $\text{SnO}_2$  and the selenidation/reduction reaction between Sn

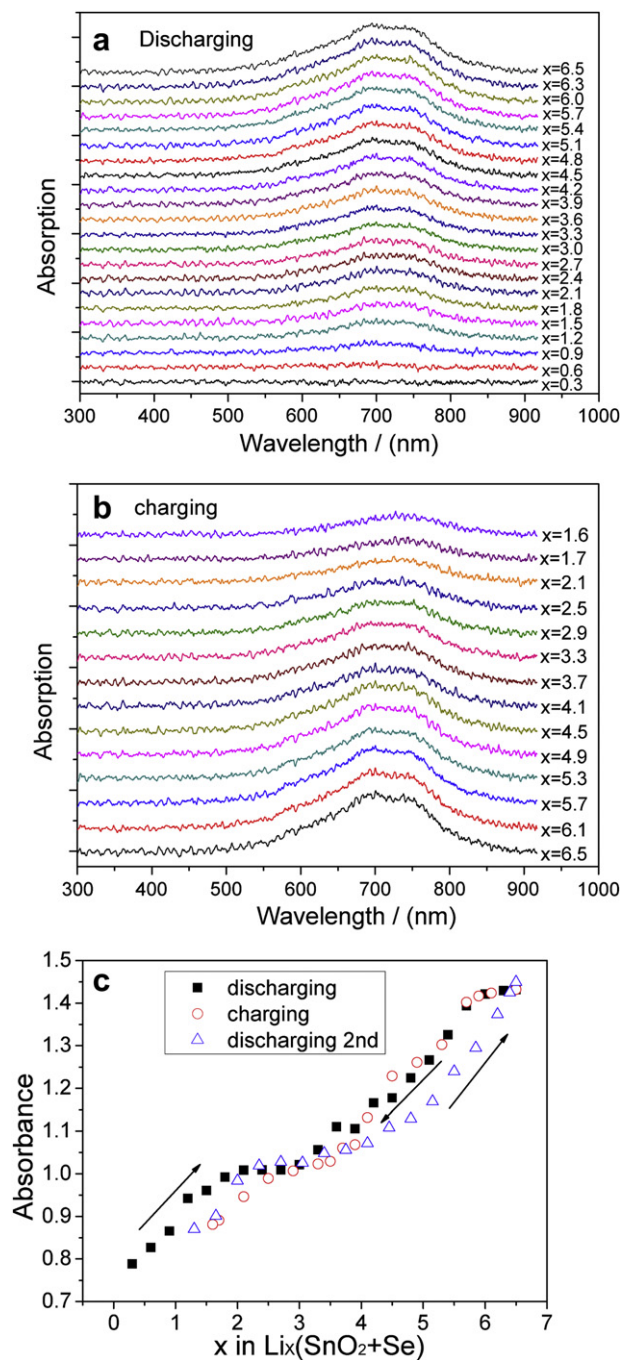

Fig. 6. Selected *in situ* UV-Vis absorption spectra obtained (a) during first discharging of  $\text{SnO}_2$ -Se to 0.01 V and (b) during charging of  $\text{SnO}_2$ -Se to 3.0 V; (c) Absorbance at 698 nm as a function of  $x$  value of reacted Li.

and  $\text{SnSe}$ . In reactions (5) and (6), it is convinced that Sn has fully reacted with  $\text{Li}_2\text{O}$  and  $\text{Li}_2\text{Se}$  based on the high reversible capacity and the characterization of SAED. It is estimated that about 27.4%  $\text{Li}_2\text{O}/\text{Li}_2\text{Se}$  doesn't participate in the electrochemical reaction with metal Sn. This should be responsible for the irreversible capacity in the initial cycle. But the residual  $\text{Li}_2\text{O}/\text{Li}_2\text{Se}$  could buffer the volume change and release the inner stress during phase transition in subsequent cycles, which leads to the prominent capacity retention. It is believed that the electrochemical performance of nano-composite  $\text{SnO}_2$ -Se thin film can be improved further after

optimizing the molar ratio of  $\text{SnO}_2$  to Se. The fact that only 19.3% of the reversible discharge capacity was declined during the initial 100th cycles have demonstrated that it is a very effective way to add Se into  $\text{SnO}_2$  for the purpose of improving cycle performance. If comparing with the data reported previously, nanosized  $\text{SnO}_2$  always has a large capacity loss upon repeated cycling. For example, Fan et al. [16] showed that only 42.8% of the capacity was reserved for an ONTC electrode over 30th cycles. The capacity of the  $\text{SnO}_2\text{--MnO}$  composite [18] fade from an initial capacity of  $1188 \text{ mAh g}^{-1}$  to  $656 \text{ mAh g}^{-1}$  after 30th cycles. In the charging process, not all Sn can react with  $\text{Li}_2\text{O}$  and come back to  $\text{SnO}_2$ . It is a partly reversible process with the gradual formation of inactive  $\text{Li}_2\text{O}$  during the cycles. This will result in a large capacity loss of nanosized tin oxide-based materials. Apparently, nanocomposite  $\text{SnO}_2\text{--Se}$  thin film as an anode exhibits the superior cycle performance. In the present case, nanosized metal tin could drive the decomposition of  $\text{Li}_2\text{Se}$  instead of the “dead” inactive  $\text{Li}_2\text{O}$  to hold the high reversible capacity. Meantime, the inactive  $\text{Li}_2\text{O}$  could be considered as the matrix-glue holding small tin particles to cushion the volume change of the Li–Sn alloys for the cyclability improvement. This kind of electrochemical reaction mechanism of  $\text{SnO}_2\text{--Se}$  with lithium may reopen new opportunities in this fascinating field of storing Li for Li-ion batteries.

#### 4. Conclusions

Nanocomposite  $\text{SnO}_2\text{--Se}$  thin film has been fabricated by pulsed laser deposition for the first time. The addition of Se into  $\text{SnO}_2$  has lead to a higher reversible capacity and better cycle performance compared to pure  $\text{SnO}_2$  and  $\text{SnSe}$ . Galvanostatic cycling showed a large reversible capacity around  $958.8 \text{ mAh g}^{-1}$ . The electrochemical reaction mechanisms of  $\text{SnO}_2\text{--Se}$  with lithium can be concluded as following: after the discharge process,  $\text{Li}_{4.4}\text{Sn}$ ,  $\text{Li}_2\text{O}$  and  $\text{Li}_2\text{Se}$  were produced. After the recharge process,  $\text{SnO}_2$  and  $\text{SnSe}$  were formed. Subsequent cycles involve the reversible oxidation/reduction reaction of  $\text{SnO}_2$  and selenidation/reduction reaction of  $\text{SnSe}$ . Residual  $\text{Li}_2\text{O}/\text{Li}_2\text{Se}$  after initial discharge may play an important role in the improvement of its cyclic performance. High reversible capacity and good stable cycle make nanocomposite  $\text{SnO}_2\text{--Se}$  a promising anode for high energy density Li-air cells.
